ABSTRACT

In this study, biostratigraphy and paleoecology of the Asmari Formation have been investigated. The study area is located in the Izeh zone, Zagros Basin. Four outcrop sections (Halayjan, Kuh Shur, Kuh-e Bad and Gharibi Ha) have been sampled. Based on distribution of the larger benthic and planktonic foraminifera, five assemblage zones have been recognized. Assemblages 1 and 2 indicate Chattian; assemblage 3 is restricted to Aquitanian and assemblages 4 and 5 suggest Burdigalian. During the Chattian, the carbonate deposits of the Asmari Formation are mostly composed of coralline red algae and large and flat benthic foraminifera. The common components of the Aquitanian are abundant imperforate foraminifera and Favreina asmaricus. The Burdigalian is characterized by coral, coralline algae, and perforate and imperforate foraminifera. During the Burdigalian toward the SE of study area (Gharibi Ha section), the shallow water deposits are abruptly overlain by pelagic limestone. It is interpreted as the result of a regional tilting that started in the upper part of the Burdigalian.

The biotic associations suggest that carbonate sedimentation occurred in tropical to subtropical waters under oligotrophic to mesotrophic conditions. The carbonate grain associations in the Asmari Formation suggest heterozoan association. According to paleoecological parameters (such as: nutrient, depth, light and salinity) in the study area, the Asmari Formation belongs to nanno-foralgal to foramol association which were deposited in slightly hyper to normal saline environment. In the euphotic zone, abundant imperforate foraminifera are present. Basinward, lens shaped rotalids developed in mesophotic conditions, and large lepidocyclinid-nummulitids characterize the sediments of the deeper oligophotic zone.

Keywords: Asmari Formation, Oligocene–Miocene, biostratigraphy, paleoecology, larger benthic foraminifera, Zagros Basin.

RESUMEN

En este estudio, investigamos la bioestratigrafía y paleoecología de la Formación Asmari. El área de estudio se localiza en la zona de Izeh, Cuenca de Zagros. Cuatro secciones en afloramientos fueron muestreadas (Halayjan, Kuh Shur, Kuh-e Bad y Gharibi Ha). Con base en la distribución de grandes foraminíferos bentónicos y planctónicos, cinco zonas de asociación fueron reconocidas. Las asociaciones 1 y 2 indican una edad correspondiente al Chattiano; la asociación 3 está restringida al Aquitaniano, y las asociaciones 4 y 5 sugieren una edad correspondiente al Burdigaliano. Durante el Chattiano, los depósitos de carbonato de la Formación Asmari, fueron compuestos principalmente por algas coralinas y rojas, así como por foraminíferos bentónicos grandes y aplanaos. Los componentes comunes en el Aquitaniano son abundantes foraminíferos imperforados y Favreina asmaricus. El Burdigaliano se caracteriza por corales, algas coralinas y foraminíferos perforados e imperforados. Durante el Burdigaliano, hacia el SE del área de estudio (sección Gharibi Ha), los depósitos someros son sobreyacidos abruptamente por caliza pélagica. Lo anterior se interpreta como el resultado de una inclinación regional, que inició en la parte superior del Burdigaliano.

Las asociaciones bióticas sugieren que la sedimentación de carbonatos ocurrió en aguas tropicales a subtropicales, en condiciones oligotróficas a mesotróficas. Las asociaciones de granos de carbonato en la Formación Asmari, sugieren una asociación heterozoica. Con base en parámetros paleoecológicos en el área de estudio (tales como: nutrientes, profundidad, iluminación y salinidad), la Formación Asmari corresponde a una asociación de nanoplancton/foraminíferos – foraminíferos/algas, a foraminíferos/moluscos, depositadas en un ambiente con condiciones ligeramente hiposalinas a salinas normales. En la zona eufótica se presentan abundantes foraminíferos imperforados. Hacia la parte profunda de la Cuenca se desarrollaron rotálicos lenticulares, bajo condiciones mesofóticas, y grandes lepidociclinas-numulites, caracterizan a los sedimentos de la profunda zona oligofótica Burdigaliano.

Palabras clave: Formación Asmari, Oligoceno - Mioceno, bioestratigrafía, paleoecología, grandes foraminíferos bentónicos, Cuenca de Zagros.

1. Introduction

The Zagros mountain belt of Iran, a part of the Alpine–Himalayan system, extends from the NW Iranian border to SW Iran, up to the Strait of Hormuz (Figure 1A) (Heydari *et al.*, 2003). It can be divided into a number of zones (Lurestan, Izeh, Dezful Embayment, Fars, High Zagros), which differ according to their structural style and sedimentary history (Figure 1B). The Asmari Formation is a stratigraphic unit, mostly composed of limestone with subordinate sandstone and shale of approximately Oligocene–Early Miocene age. This formation was developed regionally across the Zagros Mountain range, prograding from the north and the south into the Eocene–Early Miocene Pabdeh Formation (James and Wynd, 1965; Seyrafian *et al.*, 1996). The Asmari Formation is the main petroleum reservoir in southwest Iran (Beydoun *et al.*, 1992).

Lithologically, the Asmari Formation, at the type section in Tang-e Gel-e Tursh (Valley of Sour Earth) on the southwestern flank of the Kuh-e Asmari anticline, consists of 314 m of mainly limestone, dolomitic limestone and argillaceous limestone (Motiei, 1993). The shallow marine limestones of the Asmari Formation were conformably deposited over the Pabdeh Formation in the southwestern part of the Zagros Basin (Figure 2) and also unconformably covered the Jahrum and Shahbazan Formations to the northeastern part in the Fars and Lurestan regions (Figure 2). The Oligocene–Miocene in SW Iran is mostly characterized by exclusively shallow water carbonates.

In all studied sections the contact of the Asmari Formation with the underlying Pabdeh Formation is transitional and conformable. The upper contact with Gachsaran Formation is conformable in all studied sections. The Asmari Formation in the study area is mainly composed of thick to medium bedded and massive limestone and subordinate marl and dolomitic limestone intercalations. The overall thickness of the formation vary from northwest to southeast including 330 m, 325 m,

415 m and 416 m in the Halayjan, Kuh Shur, Kuh-e Bad and Gharibi Ha, respectively.

The biostratigraphy of the Asmari Formation was outlined by Wynd (1965) and reviewed by Adams and Bourgeois (1967). Adams and Bourgeois (1967) introduced four assemblage zones for the Asmari Formation (Table 1). They did not differentiate Rupelian from Chattian. These two reports were used by many authors (*e.g.*, Seyrafian, 2000; Vaziri-Moghaddam *et al.*, 2006; Amirshahkarami *et al.*, 2007a, b).

Recently, Ehrenberg *et al.* (2007), Laursen *et al.* (2009) and Van Buchem *et al.* (2010) conducted strontium isotope dating to improve the biostratigraphic ages for the Asmari Formation across most parts of the Zagros basin (Izeh zone and Dezful Embayment) (Table 2). This biozonation is used by many recent authors (*e.g.*, Allahkarampour Dill *et al.*, 2010; Van Buchem *et al.*, 2010; Sooltanian *et al.*, 2011; Rahmani *et al.*, 2012). The biozonation scheme of Laursen *et al.* (2009) and Van Buchem *et al.* (2010) have some basic differences compared to the old scheme (Adams and Bourgeois, 1967). In the old scheme, the noticeable thickness of the Asmari limestone, containing *Archaias*, has been considered Aquitanian. Today this interval proved to be Oligocene. Also in the biozonation of Laursen *et al.* (2009) and Van Buchem *et al.* (2010), the Oligocene sediments are divided to Rupelian and Chattian.

The area of the new biostratigraphic studies which used the biozonation of Laursen *et al.* (2009) and Van Buchem *et al.* (2010) is very small in comparison to the total area of the Asmari basin (more than 150 km × 700 km). There are a lot of areas with unpublished sections for which the new biozonation should be considered. The studied area of this research is one of those areas with well preserved and untouched outcrop sections. The data obtained from biostratigraphic studies in this area will be used for the future regional study. The abundance of large benthic foraminifera in the limestones of the Asmari Formation offers an excellent opportunity to study paleoenvironmental controls on larger benthic foraminiferal assemblages in

detail. Sedimentary successions, representing the Oligocene–Miocene interval, allow us to evaluate the influence of change in ecological parameters through time.

The objectives of this study are (1) to reconstruct a coherent biostratigraphic framework for the carbonate deposits of the Asmari Formation in the studied area based on available biozonation schemes (Cahuzac and Poignant, 1997; Laursen *et al.*, 2009; Van Buchem *et al.*, 2010) (Tables 1 and 2), and (2) to present the paleoenvironmental factors which affect the distribution of biogenic components of the Asmari Formation.

2. Material and method

To achieve the aim of this study, four unpublished sections (Halayjan, Kuh Shur, Kuh-e Bad and Gharibi Ha) (Figures 1C and 3–5) were measured, described and sampled for paleontological and petrographical studies. The measurement was carried out using Jacob's staff. The description logs, containing lithology, texture and components (with hand lens), bedding and thickness, was prepared in the field. Around 1000 thin sections were prepared and studied to investigate texture (Dunham, 1962; Embry and Klovan, 1971) components and species identification. In this paper, LBF are used to date the carbonates using biostratigraphical zo-

Biozonation of the Asmari Formation

nation (Wynd, 1965; Adams and Bourgeois, 1967; Laursen et al., 2009; Van Buchem et al., 2010) and comparisons with the global Oligocene/Miocene zonation of Cahuzac and Poignant (1997) (Tables 1, 2 and 3).

To have the possibility of future reinterpretation and data control, a data set containing ~10000 digital photos were prepared by using the Nikon microscope suite in the National Iranian South Oil Company lab. Nearly all of components are documented in these photos. These photos were classified and used for biostratigraphy and paleoecological interpretation. Based on this method, for every component mentioned in the biostratigraphic log, one or more photo is available.

3. Biostratigraphy

The Oligocene to Miocene benthic and planktonic foraminiferal assemblages, including a total of 17 genera and 23 species, were analyzed to establish the biostratigraphic framework of the Asmari For-

mation in the studied sections (Figures 6, 7, 8 and 9). From base to top, five Assemblage Zones were recognized (Figures 6, 7, 8, 9 and 10).

3.1. ASSEMBLAGE 1

This assemblage is present in all sections and consists of *Eulepidina dilatata*, *Eulepidina elephantina*, *Eulepidina* sp., *Nephrolepidina tournoueri*, *Nephrolepidina* sp., *Lepidocyclus* sp., *Heterostegina costata*, *Heterostegina* sp., *Spiroclypeus blanckenhorni*, *Spiroclypeus* sp., *Operculina complanata*, *Operculina* sp., *Neorotalia viennoti*, *Amphistegina* sp., *Ditrupa* sp. and globigerinids (Figure 11). This assemblage is correlated with the *Lepidocyclus-Operculina-Ditrupa* Assemblage Zone of Laursen et al. (2009) and Van Buchem et al. (2010), and to the SBZ 22 of Cahuzac and Poignant (1997).

Based on Laursen et al. (2009) this assemblage is attributed to the Rupelian-Chattian. However, based on Ehrenberg et al. (2007) who believes that the presence of *Spiroclypeus blanckenhorni* indicates a Chattian age, the age of this zone must be limited to the Chattian.

3.2. ASSEMBLAGE 2

This assemblage is recorded in Kuh-e Bad and Gharibi Ha sections. The most diagnostic species include: *Archaias kirkukensis*, *Archaias hensonii*, *Archaias asmaricus*, *Archaias* sp., *Miogypsinoides* sp., *Elphidium* sp.1, *Peneroplis* sp., *Astrotrillina* sp., *Dendritina rangi*, *Meandropsina iranica*, *Meandropsina anahensis*, *Meandropsina* sp., *Amphistegina* sp., *Globigerina* spp. (Figures 12 and 13). These microfauna correspond to the *Archaias asmaricus-Archaias hensonii-Miogypsinoides complanatus* Assemblage Zone of Laursen et al. (2009) and Van Buchem et al. (2010), and to the SBZ 23 of Cahuzac and Poignant (1997), and indicate Chattian.

3.3. ASSEMBLAGE 3

This assemblage occurred in all sections and is defined by the concurrence of *Astrotrillina howchini*, *Astrotrillina asmariensis*, *Amphistegina* sp., *Aus-*

trotillina sp., *Peneroplis farsensis*, *Peneroplis evolutus*, *Peneroplis thomasi*, *Peneroplis* sp., *Miogypsina irregularis*, *Miogypsina* sp., *Miogypsinoides* sp., *Elphidium* sp.14, *Elphidium* sp.1, *Dendritina rangi*, *Meandropsina iranica*, *Meandropsina* sp., *Favreina asmaricus* (Figures 12 and 13) and represents the *Miogypsina*–*Elphidium* sp.14–*Peneroplis farsensis* Assemblage Zone of Laursen *et al.* (2009) and Van Buchem *et al.* (2010), and to the SBZ 24 of Cahuzac and Poignant (1997). This zone is restricted to Aquitanian.

3.4. ASSEMBLAGE 4

This assemblage is recorded in all sections. The most important fauna are: *Borelis melo curdica*, *Borelis melo melo*, *Borelis* sp., *Meandropsina iranica*, *Meandropsina anahensis*, *Meandropsina* sp., *Austrotrocholina* sp., *Dendritina rangi*, *Peneroplis farsensis*, *Peneroplis* sp., *Peneroplis evolutus*, *Elphidium* sp.14, *Elphidium* sp.1, *Miogypsina* sp., *Miogypsinoides* sp., *Miogypsinoides* cf. *dehaarti*, *Amphistegina* sp., *Operculina complanata*, *Operculina* sp., *Globigerina* spp., *Globigerinoides* spp. (Figures 12 and 13). This zone is restricted to the Burdigalian based on the first appearance of *Borelis melo curdica*, *Borelis melo melo* (Cahuzac and Poignant, 1997; Laursen *et al.*, 2009; Van Buchem *et al.*, 2010). Although the presence of *Miogypsinoides* has been reported by Adams and Bourgeois (1967) in Burdigalian time, it is not reported in this time in the recent regional biostratigraphic study of the Asmari Formation introduced by Laursen

et al. (2009) and Van Buchem *et al.* (2010). In this study, we have reported abundant occurrences of this genus (*Miogypsinoides*) in the study area during the Burdigalian.

3.5. ASSEMBLAGE 5

This assemblage occurs from 344 to 415 m of the Asmari Formation, only in Gharibi Ha section, and consists of *Globorotalia obesa*, *Globigerina praebullioloides*, *Globigerinoides immaturus*, *Globigerinoides trilobus*, *Globigerinoides diminutus*, *Catapsydrax* sp., *Globigerinoides* spp. (Figure 13). This assemblage overlies 78 m shallower carbonates of Burdigalian age. The top of this assemblage is marked by anhydrite deposits of the base of the Gachsaran Formation. *Globigerina* spp.–*Turborotalia cerroazulensis*–*Hantkenina* Assemblage Zone was introduced by Laursen *et al.* (2009) (Table 2). The age of this Assemblage Zone is Late Eocene–Early Oligocene. However, Wynd (1965) introduced *Globigerina* spp. Assemblage Zone (Table 1) from different intervals of the Asmari Formation in different localities in the Zagros Basin. The age of this zone was considered Late Eocene–Oligocene–Early Miocene based on its relationship to the underlying and overlying sediments. We recorded abundance planktonic foraminifera in Gharibi Ha section from above the *Borelis melo curdica*–*Borelis melo melo* Assemblage Zone. The age of this Assemblage Zone is considered Burdigalian based on its planktonic

foraminifera (Iaccarino *et al.*, 2005) and underlying Burdigalian shallow carbonate sediments.

4. Paleoecological interpretation

Paleoecology of Oligocene and Miocene carbonate platforms are studied by many authors with different points of view (*e.g.*, Hallock and Glenn, 1986; Hottinger, 1997; Pedley, 1998; Geel, 2000; Pomar, 2001; Romero *et al.*, 2002; Beavington-Penney and Racey, 2004; Cosovic *et al.*, 2004; Pomar *et al.*, 2004; Pomar and Hallock, 2008; Brandano

et al., 2009a, b; Bassi and Nebelsick, 2010; Flügel, 2010; Pomar *et al.*, 2012). In this study the most significant paleoecological elements such as salinity, light penetration, nutrients, temperature and water depth are discussed in detail.

4.1. CHATTIAN

In the Chattian succession of the studied area the most significant and dominant biogenic components are coralline red algae; large, flat and perforate benthic foraminifera (*Operculina*, *Heterostegina*, *Eulepidina*, *Nephrolepidina*, *Spiroclypeus*, *Amphistegina*

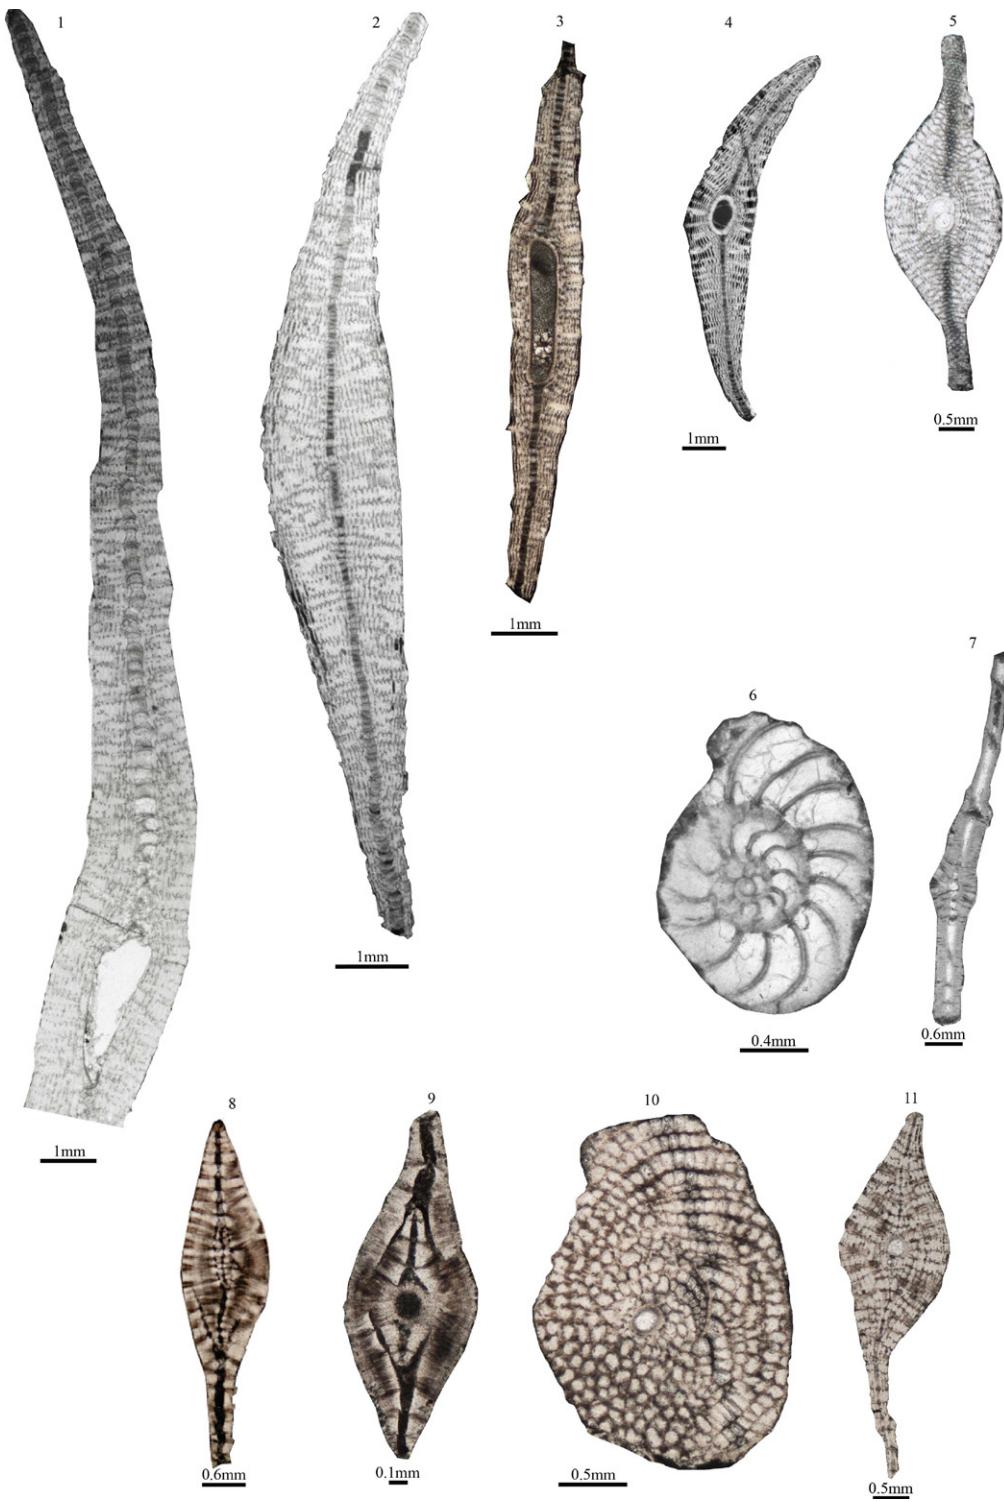

Figure 11 Photomicrograph of some selected fauna of the Asmari Formation in the studied sections. 1) *Eulepidina elephantina* (Lemoine and Douville, 1904), axial section, sample number K2; 2) *Eulepidina* sp., subaxial section, sample number K15; 3) *Eulepidina dilatata* (Michelotti, 1861), axial section, sample number G8; 4) *Eulepidina dilatata*, axial section, sample number K3; 5) *Nephrolepidina tournoueri* (Lemoine and Douville, 1904), axial section, sample number H0; 6) *Operculina* sp., subequatorial section, sample number H17.5; 7) *Operculina complanata* (Defrance, 1822), axial section, sample number K22; 8) *Heterostegina* sp., subaxial section, sample number G54; 9) *Heterostegina* sp., axial section, sample number G50; 10) *Spiroclypeus blankenhorni* (Henson, 1937), equatorial section, sample number G61; 11) *Spiroclypeus blankenhorni* (Henson, 1937), axial section, sample number G67.

Fornasini, 1904), subequatorial section, sample number K141; 13) *Dendritina rangi* (d'Orbigny emend. Fornasini, 1904), subaxial section, sample number K68.

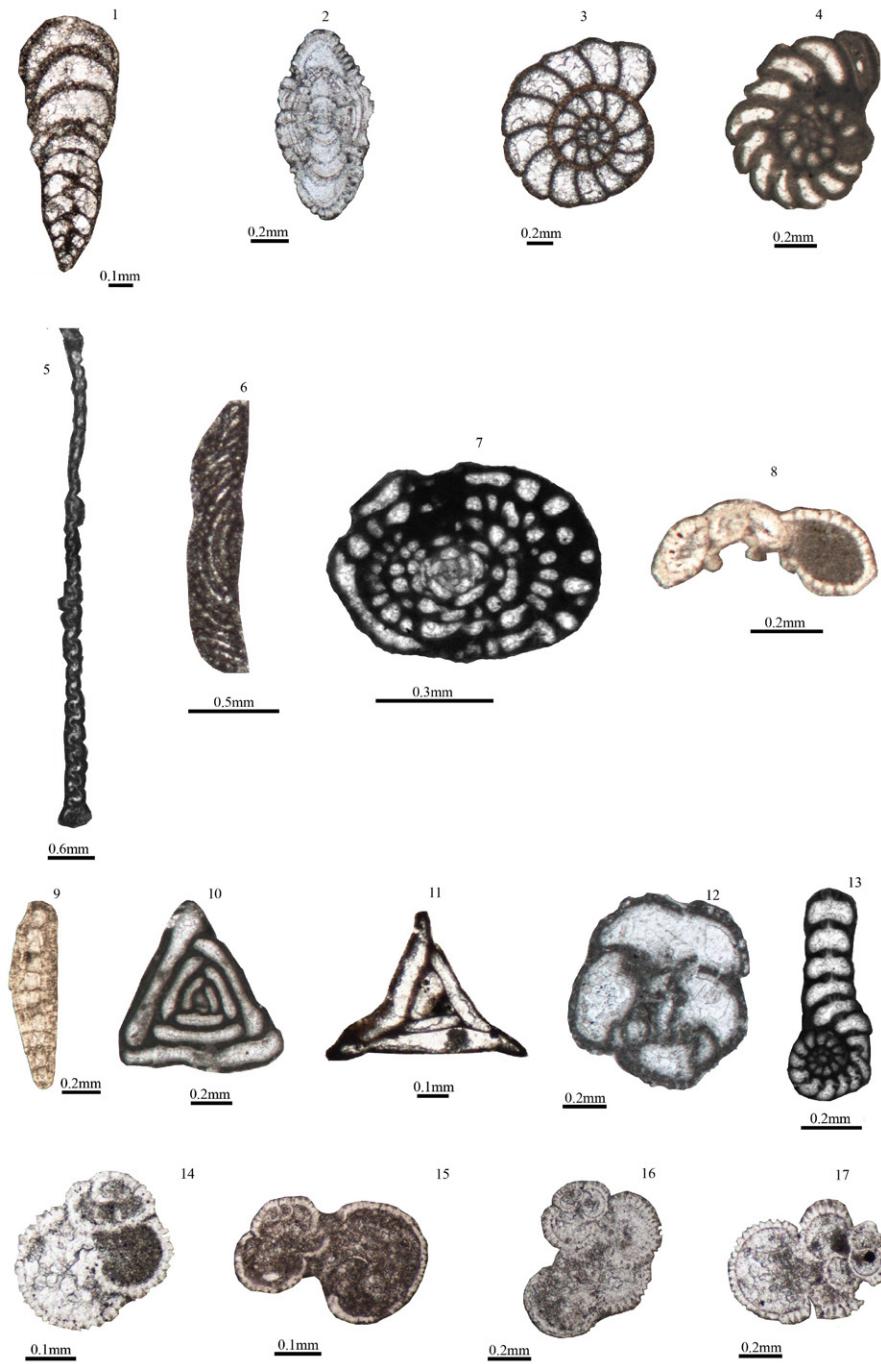

Figure 13 Photomicrograph of some selected fauna of the Asmari Formation in the studied sections. 1) *Bigenerina* sp., Longitudinal section, sample number G288; 2) *Elphidium* sp.14, axial section, sample number G238; 3) *Elphidium* sp.1, equatorial section, sample number G274; 4) *Peneroplis* cf. *farsensis* (Henson, 1950), equatorial section, sample number K69; 5) *Meandropsina iranica* (Henson, 1950), subaxial section, sample number H276; 6) *Meandropsina anahensis* (Henson, 1950), oblique equatorial section, sample number G128; 7) *Borelis melo curdica* (Reichel, 1937), axial section, sample number K171.5; 8) *Discorbis* sp., axial section, sample number H186; 9) *Miogypsinoides* sp., axial section, sample number K282; 10) *Triloculina trigonula* (Lamarck, 1804), equatorial section, sample number K121; 11) *Triloculina tricarinata* (d'Orbigny, 1826), equatorial section, sample number G312; 12) *Valvulinid* sp., Longitudinal section, sample number H72; 13) *Spiroloculina* cf. *cylindracea* (Henson, 1950), equatorial section, sample number KS41; 14) *Globigerina* sp., axial section, sample number G396; 15) *Globigerinoides trilobus* (Reuss, 1850), axial section, sample number G367; 16) *Globigerinoides subquadratus* (Broennimann, 1954), axial section, sample number G386; 17) *Globigerinoides diminutus* (Bolli, 1957), axial section, sample number G414.

and *Lepidocydina*); and imperforate foraminifera (*Archaias*, *Peneroplis*, *Dendritina*). Other skeletal grains consist of echinoid, gastropod, bryozoan and bivalve fragments (Table 4). Accordingly, the paleoecological conditions of the Asmari Formation during the Chattian could be interpreted as follows:

Nummulitids, lepidocylinids and red algae thrived in oligophotic to mesophotic mid-ramp environments (Kuh-e Bad and Gharibi Ha) preferably at water depths that ranged from 40 to 80 m (Bosence, 1983; Hottinger, 1997; Beavington-Penney and Racey, 2004).

Occurrence of large perforate benthic foraminifera (*Eulepidina*, *Heterostegina*, *Neorotalia*, *Amphistegina*), coralline red algae (*Lithophyllum* and *Lithothamnion*), imperforate foraminifera (*Archaias*, *Peneroplis*, *Dendritina*, *Astrotrillina*, miliolids) and molluscs (oysters, other bivalves, gastropods) in Kuh Shur, Kuh-e Bad and Gharibi Ha sections indicate normal to higher sea water salinity in inner ramp setting (Flügel, 2010; Allahkarampour Dill *et al.*, 2012) and could be consider as foralgal to foramol association (Wilson and Vecsei, 2005), (Figure 14) (Table 4).

The carbonates of the Asmari Formation in the study area were replaced by basinal marl and shale of the Pabdeh Formation towards the center of interashelf (toward the south). In the studied sec-

tions a major part of carbonate of the Asmari Formation (Chattian in age) in the Gharibi Ha and Kuh-e Bad sections is replaced by basinal marl and shale of the Pabdeh Formation in Halayjan section.

4.2. AQUITANIAN

The Aquitanian is characterized by abundant imperforate benthic foraminifera such as *Dendritina*, *Peneroplis*, *Meandrospina*, *Astrotrillina* and miliolids. Perforate foraminifera such as *Miogypsina*, *Miogypsinoides* and *Elphidium* are also present as subordinate components. Mollusks and echinoids are also present. The Aquitanian biota of the studied area represents a foramol assemblage (Lees and Buller, 1972) (Figure 15) (Table 4). These foraminifera indicate a low energy and hypersaline condition and interpreted as a semi-restricted lagoon setting (inner ramp) (Wilson, 1975; Geel, 2000; Corda and Brandano, 2003; Bassi *et al.*, 2007; Flügel, 2010).

This biotic association indicates a deposition within the photic zone, in a sea-grass-dominated environment as suggested by the presence of epiphytic porcellaneous foraminifera such as *Peneroplis* and miliolids (Wilson, 1975; Langer, 1993; Beavington-Penney and Racey, 2004; Reich *et al.*, 2015). Further evidence for sea grass can be

Amp: *Amphistegina*, Arc: *Archaias*, Aus: *Astrotrillina*, Biv: Bivalve, Bry: Bryozoan, Den: *Dendritina*, Dis: *Discorbis*, Ech: Echinoid fragment, Elp: *Elphidium*, Eul: *Eulepidina*, Gas: Gastropod, Het: *Heterostegina*, Mil: Miliolids, Ope: *Operculina*, RA: non-articulated red-algal fragments, Spi: *Spiroclypeus*, Spr: *Spiroloculina*, Val: *Valvulinid*.

given by the poorly sorted and micrite-rich textures and absence of sedimentary structures. The associated fauna (*Peneroplis*, *Borelis*, discorbids and thick samples of *Amphistegina*) are also typical for seagrass meadows (Murray, 1973; Brasier, 1975; Beavington-Penney and Racey, 2004; Brandano *et al.*, 2009a; Reuter *et al.*, 2010; Pomar *et al.*, 2014). One of the most important and excellent markers for the Aquitanian is *Favreina asmaricus* (coprolitic facies) (Figure 15) (Table 4) with occurrences related to the particular environmental condition (isolated hypersaline basins for part of the time) (Laursen *et al.*, 2009; Van Buchem *et al.*, 2010). In the more saline interval *Favreina asmaricus* is common (Mossadegh *et al.*, 2009). The presence of porcellaneous benthic foraminifera with *Favreina asmaricus*, coralline algae, coral, bryozoa and echinoderm fragments are common in lower parts of the Aquitanian sediments, especially in Halay-

jan section. *Favreina asmaricus* is rare in Kuh Shur, Kuh-e Bad and Gharibi Ha sections which are situated in shallower parts of the Asmari intrashelf basin.

The *Favreina* limestone is a well known facies of intrashelf margin of the Aquitanian. It has been interpreted as restricted condition of interashelf basin (Van Buchem *et al.*, 2010).

4.3. BURDIGALIAN

In the study area, the common biota of the Burdigalian are coral, coralline algae, *Amphistegina*, *Miogypsinoides*, *Meandropsina*, *Elphidium*, *Borelis*, *Dendritina*, *Peneroplis*, miliolids and mollusc debris (Table 4). A similar assemblage was reported from the inner ramp of the Miocene sediments of the Central Apennines (Corda and Brandano, 2003) and from the Early Oligocene deposits of

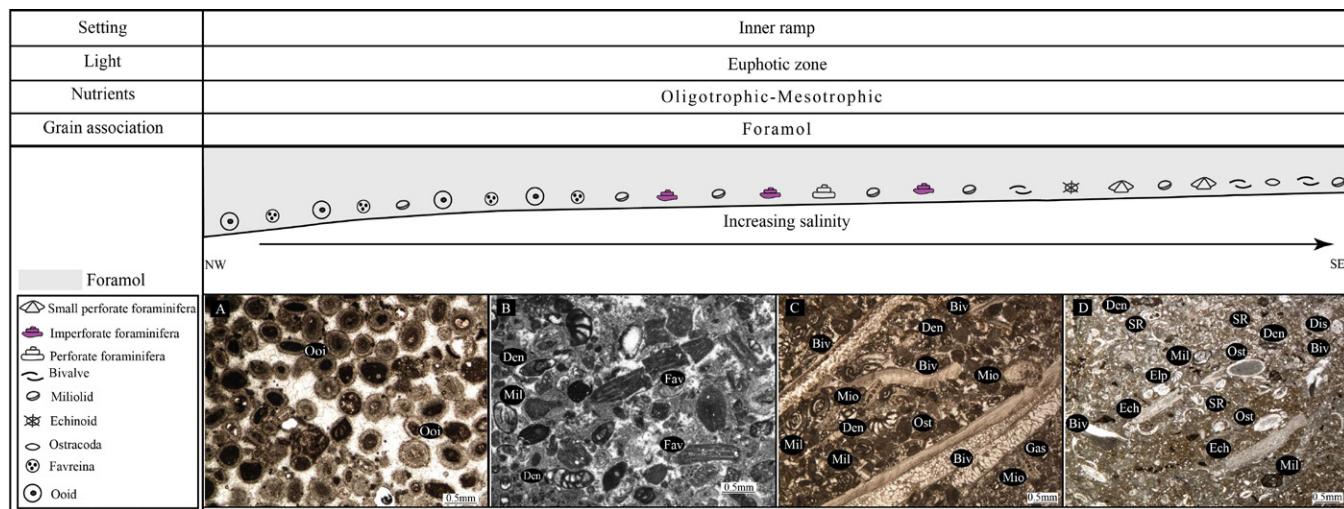

Figure 15 Sedimentary and paleoecological profile of the Asmari Formation during the Aquitanian time. the Lower Inn Valley (Nebelsick *et al.*, 2001). The abundance of larger benthic foraminifera (*Borelis*, *Peneroplis*, *Dendritina*, *Heterostegina*, *Operculina*) and zooxanthellate corals indicate mesophotic to euphotic condition (Halfar *et al.*, 2004; Pomar *et al.*, 2004; Pomar and Hallock, 2008; Brandano *et al.*, 2009b; Mazzucchi and Tomassetti, 2011; Tomassetti and Brandano, 2013). During the Burdigalian a slightly restricted lagoon became established over the entire width of the platform in the SW (*e.g.* Dezful Embayment) characterized by proliferation of imperforate foraminifera (Rahmani *et al.*, 2009).

At Kuh-e Bad section, planktonic foraminifera (rare), coral, corallinacean algae, *Heterostegina* and *Operculina* are also present in the Burdigalian assemblage (Table 4). Towards the east of studied area (figures 1C and 10) in Gharibi Ha section, planktonic foraminifera facies is more common in the upper part of the Burdigalian. These faunal associations represent a nannoform assemblage (Lees and Buller, 1972) (Table 4). The nannoform (aphotic zone-outer shelf) association occurred in a deeper water depositional setting. The existence of abundant planktonic foraminifera indicates that the sediment of the upper part of the Burdi-

galian was deposited in deeper-water environment in Gharibi Ha section (Figures 16 and 17).

5. Discussion

Our detailed analysis of the stratigraphy and paleoecology show that the Asmari Formation was deposited on a carbonate ramp in tropical to subtropical latitudes (10° to 30°) (Vaziri-Moghaddam *et al.*, 2006; Heydari, 2008; Allahkarampour Dill *et al.*, 2010; Vaziri-Moghaddam *et al.*, 2010; Shabafrooz *et al.*, 2015a, b). The differentiation between non-tropical and tropical carbonates is mainly based on analysis of skeletal components (Lees and Buller, 1972; Carannante *et al.*, 1988; Nelson, 1988). The foraminiferal associations such as *Dendritina*, *Archaias*, *Borelis*, *Spiroclypeus*, *Lepidocyrtina*, *Neorotalia*, and *Amphistegina* within the Asmari Formation suggest that carbonate sedimentation took place in tropical to subtropical latitudes. The symbiont bearing larger foraminifera are known to thrive in tropical waters (Langer and Hottinger, 2000). According to Heydari (2008) the Zagros Basin was located close to 30° N during the Oligocene-Miocene. This idea suggests that carbonate

sedimentation of the Asmari Formation took place in tropical to subtropical waters.

Zooxanthellate corals and large benthic foraminifera are the most successful shallow, benthic

carbonate producers in clear, tropical-subtropical oceanic waters (Hallock, 2001). Zooxanthellate corals and the LBF (*Borelis*, *Archaias*, *Peneroplis*, *Lepidocyclusina*) assemblages of the Asmari Formation

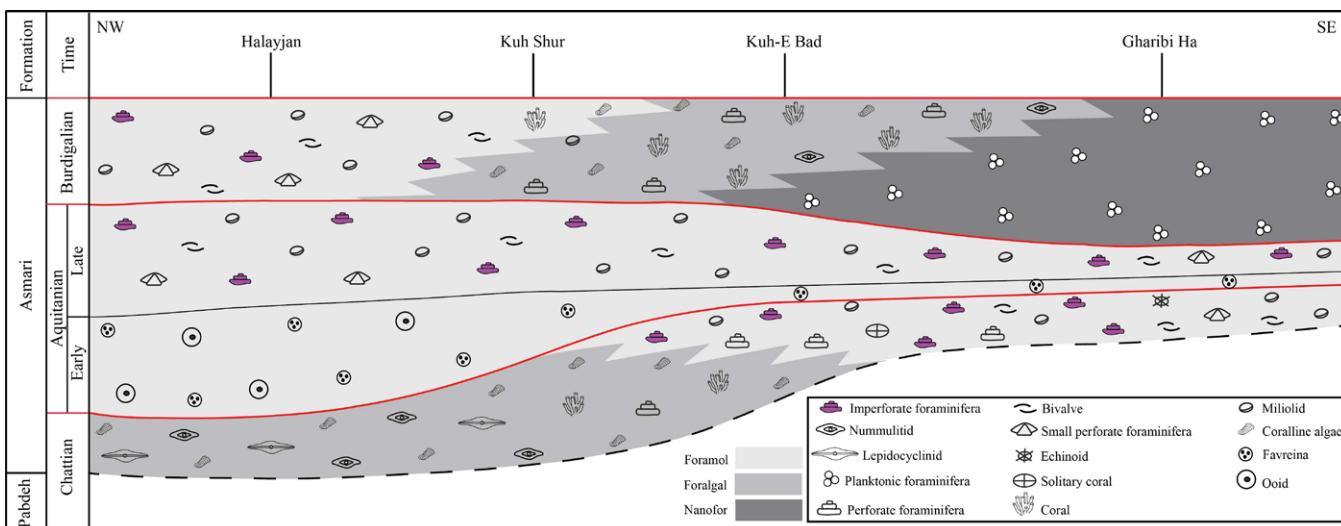

Figure 17 Depositional and paleoecology conceptual model of the Asmari Formation during the Chattian - Burdigalian.

thrive in oligotrophic to possibly slightly mesotrophic waters (Langer and Hottinger, 2000; Halfar *et al.*, 2004; Pomar *et al.*, 2004; Bassi and Nebelsick, 2010).

Oligotrophic to mesotrophic conditions in the inner ramp setting (Chattian–Burdigalian) lead to the occurrence of larger imperforate foraminifera such as *Archaias*, *Borelis*, *Peneroplis* and *Astrotrillina*. These porcellaneous larger foraminifera show well lit, highly translucent, shallowest part of the photic zone. Lens shaped rotalids lived in mesophotic conditions in the middle ramp setting (Chattian), and large and flat lepidocyclinid–nummulitids characterizes the sediments of the deeper oligophotic zone in the middle ramp setting (Chattian). These assemblages of benthic foraminifera are not identified in the Kuh Shur and Halayjan sections, because of their deep-seated paleogeographical position during the Chattian (Figure 10). However, the base of the Asmari Formation deposits, from southeast to northwest, becomes younger and diachronous. Consequently, this stepwise younging could be expected in series with basinward progradation of the Asmari Formation over the basinal shale and marl of the Pabdeh Formation. Some of these progradational architectures (*e.g.* Eshgar and Gurguda clinoforms) have been documented in different parts of the Asmari depositional basin (Van Buchem *et al.*, 2010; Shabafrooz *et al.*, 2015b). During the Chattian the thickness of the Asmari Formation increases from northwest to southeast in the study area. Afterward, during the Aquitanian, the thickest interval of the formation is recorded in the Halayjan section. In the Burdigalian the thickness of the formation increases from the Halayjan section to the Kuh-e Bad and decreases towards the Gharibi Ha section (Figure 10).

The upper part of the Asmari Formation in the Gharibi Ha section (Burdigalian) is characterized by abundance of planktonic Foraminifera. This suggests that deeper-water carbonate (nannoform, oligophotic to aphotic, outer ramp) deposition was active in the Asmari Formation, in the Gharibi Ha section. The planktonic foraminifera documented within the upper part of the Asmari Formation in

the Gharibi Ha section also indicate a deposition in the tropical waters under oligotrophic conditions as suggested by the occurrence of *Globigerinoides trilobus* which proliferate in warm nutrient-poor waters (Tolderlund *et al.*, 1971; Be, 1977; Hemleben *et al.*, 1989). In the light of modern analogues, the occurrence of larger benthic foraminifera and zooxanthellate corals in the geological record is interpreted as photozoan assemblages. Nevertheless, the Asmari Formation is dominated by heterozoan assemblages. Heterozoan carbonates can develop on a carbonate ramp (Carannante *et al.*, 1988; Jones and Desrochers, 1992; Boreen and James, 1995; Feary, 1995; Brachert *et al.*, 1998). The spread of heterozoan assemblages related to the low capacity of corals to thrive in high-light conditions and to form a wave-resistant reef promoted the distribution of heterozoan assemblages (Brandano *et al.*, 2009a; Rahmani *et al.*, 2009; Allahkarampour Dill *et al.*, 2010).

Oligo-Miocene carbonates are extensive throughout SW Iran. The Dill Anticline section (Allahkarampour Dill *et al.*, 2010, 2012) and the Gachsaran and Bibi-Hakimeh oilfields (Shabafrooz *et al.*, 2015b) were selected for comparison with the studied sections. The biotic associations of the mentioned areas are quite similar to those described in the study area. They were deposited on a carbonate ramp dominated by heterozoan skeletal assemblages, in which most benthic carbonate production occurred in inner-to-middle ramp settings. The main producers were larger benthic foraminifera and red algae, but zooxanthellate corals are rare (Allahkarampour Dill *et al.*, 2010, 2012; Shabafrooz *et al.*, 2015b). This biotic association suggests that carbonate sedimentation of the Asmari Formation took place in tropical-subtropical waters under oligotrophic-mesotrophic conditions.

The other examples of the Oligocene shallow-water carbonates have been described in Malta (Brandano *et al.*, 2009a, b) and in northeastern Italy Lessini Shelf Venetian foreland basin (Bassi and Nebelsick, 2010). At these areas rotalids, miliolids and imperforate foraminifera are frequent

in the inner ramp, while red algae and lepidocyathids are abundant in the middle ramp. The foraminiferal assemblage of the Asmari Formation shows close affinities to that described by Brandano *et al.* (2009a) of the Malta carbonate platform. Such assemblages suggest that carbonate sedimentation took place in tropical to sub-tropical waters, under oligotrophic to slightly mesotrophic conditions. In the carbonate platform of the Attard Member (Brandano *et al.*, 2009a, b) and Asmari Formation, zooxanthellate corals did not form a reef framework.

As a result, the lateral facies distribution within the Asmari succession suggests that the sea level in the Chattian was relatively shallow, but deepened toward the NW region. These observations indicate that the Chattian to Aquitanian was a time of relative tectonic quiescence in this area. The lateral distribution of facies during the Late Burdigalian suggests a significant depth range, from the shallowest facies in the NW region to the most distal facies in the SE region. This pattern contrasts with subtle lateral shifts in facies characteristic of the underlying sequence, suggesting increased subsidence during this time in the SE regions (Figure 17). Previous studies (Seyrafian, 2000; Van Buchem *et al.*, 2010) mentioned that in the north Izeh area, the shallow water deposits of the Early Burdigalian are locally overlain by pelagic marls of the Late Burdigalian (*e.g.* Ghaleh Madreseh section), while in the Chidan section (Figure 1C), coral, corallinacean algae, benthic imperforate and perforate foraminifera were deposited (Van Buchem *et al.*, 2010). The deepening in the north is considered a result of a regional tilting that started in the Late Burdigalian (Van Buchem *et al.*, 2010) (Figure 17).

6. Conclusion

In this research based on the micropaleontological analysis of the larger benthic foraminifera and their distribution, five assemblage zones have been recorded. Three assemblages (1, 3, 4) are present in all sections (Halayjan, Kuh Shur, Kuh-e Bad

and Gharibi Ha). Assemblage 2 is recorded in two sections (Kuh-e bad and Gharibi Ha) and assemblage 5 is only occurred in Gharibi Ha section. Assemblages 1 and 2 indicate the Chattian age; assemblage 3 is restricted to the Aquitanian age; and assemblages 4 and 5 suggest the Burdigalian age. According to this study, the age of the Asmari Formation ranges from the Oligocene (Chattian) to Early Miocene (Aquitian–Burdigalian). The biotic associations within the Asmari Formation indicate that the lower part of the Asmari Formation (Chattian) was mostly deposited in the oligophotic–mesophotic zone, in normal saline waters. The middle and upper parts of the Asmari Formation is characterized by euphotic–mesophotic biota (except for the Gharibi Ha section, SE of study area, where the sedimentation occur in aphotic situation in Burdigalian). The oligophotic zone is characterized by large and flat lepidocyathids and nummulitids and corallinacean algae. Lens shaped rotaliids abundantly thrived in the mesophotic zone. The euphotic zone is dominated by porcellaneous larger foraminifera and indicates well lit, highly translucent, shallowest part of the photic zone.

The biotic assemblages recognized within the Asmari Formation indicate a deposition in tropical to sub-tropical waters, as suggested by the presence of diverse large benthic foraminifera. Carbonate grain associations suggest a heterozoan assemblage for the Asmari Formation. Deposition of the Asmari Formation took place under oligotrophic to mesotrophic conditions in the study area.

From the Chattian to Aquitanian was a time of relative tectonic stability in the area. The deepening in the north of the study area is considered as a result of a regional tilting that started in the Late Burdigalian.
